INTRODUCTION

According to recent reports from the National Highway Traffic Safety Administration (NHTSA) (Chen & Ye, 2010; NHTSA, 2011a) seat belt use in the United States reached a record high of 84 percent in 2009, with statewide belt use varying from 67.6 percent in Wyoming to 98.0 percent in Michigan. A major component of this success is NHTSA's effort to increase use of belts through the annual *Click it or Ticket* Safety Belt Mobilization campaigns. Each year NHTSA supports the campaign by developing a schedule, communication plan, and advertisement materials. NHTSA also provides sponsorship directly to states to help them fund local advertisement, overtime enforcement, and evaluation activities. The *Click it or Ticket* campaign is based on the idea of increasing the perceived risk of receiving a citation for failing to use a belt. The increase in perceived risk is achieved jointly through advertisements notifying the public that police will be increasing their efforts to cite belt law violators and high-visibility seat belt enforcement. Research shows that increasing the perceived chances of receiving a seat belt citation and having to pay the resulting fines can convince people to buckle up. Indeed, previous implementations of this program have been shown to increase statewide seat belt use (Solomon, Chaudhary, & Cosgrove, 2003; Solomon, Ulmer, & Preusser, 2002). The 2011 *Click It or Ticket National Mobilization* continued to target men aged 18-34. As it previous year, the campaign also targets increasing belt use at night with the tagline: "Day or Night – Click it or Ticket" (NHTSA, 2011b)

So that Minnesota can further its efforts to reduce traffic-crash-related injuries and fatalities, the state continues to participate in the nationwide safety belt mobilization campaigns. Minnesota was quite active during the *May 2011 Click It or Ticket Mobilization* campaign. According to the Minnesota Office of Traffic Safety (OTS, 2011), the Minnesota campaign took place between May 23 and June 5, 2011 and utilized about 400 police agencies. The agencies that received sponsorship from the OTS were required to conduct 50 percent of their seat belt patrols during nighttime hours (7:00 pm - 5:00 am).

In order for Minnesota to continue tracking the effectiveness of these efforts, EPIC•MRA was selected to: (1) assist in data collection efforts for two survey waves (a mini “PRE” and a full “POST” survey); (2) conduct data analysis on both surveys; and (3) report the results of the surveys. This report documents the survey design, methods, data analysis, and results.

METHODS

Sample Design

The goal of this sample design was to select observation sites that accurately represent front-outboard vehicle occupants in eligible commercial and noncommercial vehicles (i.e., passenger cars, vans/minivans, sport-utility vehicles, and pickup trucks) in Minnesota, while following federal guidelines for safety belt survey design (NHTSA, 1992, 1998). An ideal sample minimizes total survey error while providing sites that can be surveyed efficiently and economically. To achieve this goal, NHTSA guidelines allow states to omit from their sample space the lowest population counties, provided these counties collectively account for 15 percent or less of the state's total population. Therefore, all 87 Minnesota counties were rank ordered by population (US Census Bureau, 2003) and the low population counties were eliminated from the sample space. This step reduced the sample space to 37 counties.

These 37 counties were then separated into four strata. The strata were constructed by obtaining historical belt use rates and vehicle miles of travel (VMT) for each county. Historical belt use rates were determined by examining results from three previous statewide safety belt surveys conducted in Minnesota. Since no historical data were available for 22 of the counties, belt use rates for these counties were estimated using multiple regression based on educational attainment for the other 15 counties ($r^2 = .35$; US Census Bureau, 2003).¹ This factor has been shown previously to correlate positively with belt use. Hennepin County was chosen as a separate stratum because of its disproportionately high VMT. Three other strata were constructed by rank ordering each county by historical belt use rates and then adjusting the stratum boundaries until the total VMT was roughly equal within each stratum. The stratum boundaries were high belt use, medium belt use, low belt use, and Hennepin County. Hennepin County VMT was slightly lower than the collective VMTs in the other strata (94%). Stratum boundaries for the sample space are shown in Table 1.

¹ Educational attainment was defined as the proportion of population in the county over 25 years of age with a bachelor degree.

To achieve the NHTSA required precision of less than 5 percent relative error, the minimum number of observation sites for the survey was determined based on within- and between-county variances from previous belt use surveys and on an estimated 50 vehicles per observation period in the current survey. This number was then increased (N = 240) to get an adequate representation of belt use for each day of the week and for all daylight hours.

Because total VMT within each stratum was roughly equal, observation sites were evenly divided among the strata (60 each). In addition, since an estimated 29 percent of all traffic in Minnesota occurs on limited-access roadways (Federal Highway Administration, 2002), each stratum was further divided into two strata, one of which contained 17 limited access sites (exit ramps) to represent the 29% of VMT on limited access roadways and one that contained 43 roadway intersections. Thus, the sample design had a total of 8 strata.

Table 1: Listing of the Counties Within Each Stratum	
Stratum	Counties
<i>High Belt Use</i> Stratum 1: intersections Stratum 5: exit ramps	Carver, Dakota, Olmsted, Ramsey, Wright
<i>Hennepin</i> Stratum 2: intersections Stratum 6: exit ramps	Hennepin
<i>Medium Belt Use</i> Stratum 3: intersections Stratum 7: exit ramps	Beltrami, Blue Earth, Clay, Crow Wing, Freeborn, Goodhue, Kandiyohi, Nicollet, Rice, Scott, Sherburne, St. Louis, Steele, Washington
<i>Low Belt Use</i> Stratum 4: intersections Stratum 8: exit ramps	Anoka, Becker, Benton, Brown, Carlton, Cass, Chisago, Douglas, Isanti, Itasca, McLeod, Morrison, Mower, Otter Tail, Polk, Stearns, Winona

Within each intersection stratum, observation sites were randomly assigned to a location using a method that ensured each intersection within a stratum an equal probability of selection. Detailed, equal-scale road maps for each county within the sample space were obtained and a grid pattern was overlaid on the maps. The lines of the grid were separated by 1/4 inch, thus creating grid squares that were about 3/4 of a mile per side. The grid patterns were created by printing a grid design onto transparencies and uniquely identifying each grid square by two numbers, a horizontal (x) coordinate and a vertical (y) coordinate. Additional grid transparencies were printed until enough were available to cover all counties within the stratum. Each transparency was numbered to allow for a simpler grid square numbering scheme.

The 43 local intersection sites were chosen by first randomly selecting a transparency number and then a random x and a random y coordinate within the identified transparency grid sheet. If a single intersection was contained within the square, that intersection was chosen as an observation site. If the square did not fall within the stratum, or there was no intersection within the square, then a new transparency number and x, y coordinate were randomly selected. If more than one intersection was within the grid square, the grid square was subdivided into four equal sections and a random number between 1 and 4 was selected until one of the intersections was chosen. Thus, each intersection within the stratum had an equal probability of selection.

Once a site was chosen, the following procedure was used to determine the particular street and direction of traffic flow that would be observed. For each intersection, all possible combinations of street and traffic flow were determined. From this set of observer locations, one location was randomly selected with a probability equal to 1/number of locations. For example, if the intersection, was a "+" intersection, as shown in Figure 1, there would then be four possible combinations of street and direction of traffic flow to be observed (observers watched traffic only on the side of the street on which they were standing). In Figure 1, observer location number one indicates that the observer would watch southbound traffic and stand next to Main Street. For observer location number two, the observer would watch eastbound traffic and stand next to Second Street, and so on. In this example, a random number

between 1 and 4 would be selected to determine the observer location for this specific site. The probability of selecting a given standing location is dependent upon the type of intersection. Four-legged intersections like that shown in Figure 1 have four possible observer locations, while three-legged intersections like "T" and "Y" intersections have only three possible observer locations. The effect of this slight difference in probability accounts for .01 percent or less of the standard error in the belt use estimate.

Figure 1: An Example "+" Intersection Showing 4 Possible Observer Locations.

For each primary intersection site, an alternate site was also selected. The alternate sites were chosen within a five square mile area around the grid square containing the original intersection. This was achieved by randomly picking an x, y grid coordinate within an alternate site grid transparency consisting of 7 squares horizontally by 7 squares vertically, centered around the primary site. Coordinates were selected until a grid square containing an intersection was found. The observer location at the alternate intersection was determined in the same way as at the primary site.

The 17 freeway exit ramp sites for the exit ramp strata were also selected using a method that allowed equal probability of selection for each exit ramp within the stratum.¹ This was done by enumerating all of the exit ramps within a stratum and randomly selecting, without replacement, 17 numbers between 1 and the number of exit ramps in the stratum. For example, in the low belt use stratum there were a total of 75 exit

¹ An exit ramp is defined here as egress from a limited-access freeway, irrespective of the direction of travel. Thus, on a north-south freeway corridor, the north and south bound exit ramps at a particular cross street are considered a single exit ramp location.

ramps; therefore a random number between 1 and 75 was generated. This number corresponded to a specific exit ramp within the stratum. To select the next exit ramp, another random number between 1 and 75 was selected with the restriction that no previously selected numbers could be chosen. Once the exit ramps were determined, the observer location for the actual observation was determined by enumerating all possible combinations of direction of traffic flow and sides of the ramp on which to stand. As in the determination of the observer locations at the roadway intersections, the possibilities were then randomly sampled with equal probability. The alternate exit ramp sites were selected by taking the first interchange encountered after randomly selecting a direction of travel along the freeway from the primary site. If this alternate site was outside the county, or if it was already selected as a primary site, then the other direction of travel along the freeway was used.

After all sites and standing locations were randomly selected, all intersection and exit ramp sites were visited by a researcher prior to the beginning of data collection to determine their usability. If an intersection site had no traffic control device on the selected direction of travel, but had traffic control on the intersecting street, the researcher randomly picked a new standing location using a coin flip. If an exit ramp site had no traffic control on the selected direction of travel, the researcher randomly picked a travel direction and lane that had such a device.

The day of week and time of day for site observations were quasi-randomly assigned to sites in such a way that all days of the week and all daylight hours (7:00 am - 6:00 pm) had essentially equal probability of selection. The sites were observed using a clustering procedure. That is, sites that were located spatially adjacent to each other were considered to be a cluster. Within each cluster, a shortest route between all of the sites was decided (essentially a loop) and each site was numbered. An observer watched traffic at all sites in the cluster during a single day. The day in which the cluster was to be observed was randomly determined. After taking into consideration the time required to finish all sites before dark, a random starting time for the day was selected. In addition, a random number between one and the number of sites in the cluster was selected. This number determined the site within the cluster where the first observation would take place. The observer then visited sites following a

clockwise or counter-clockwise loop. The direction of the loop was determined by the project manager prior to sending the observers into the field. Because of various scheduling limitations (e.g., observer availability, number of hours worked per week) certain days and/or times were selected that could not be observed. When this occurred, a new day and/or time was randomly selected until a usable one was found. The important issue about the randomization is that the day and time assignments for observations at the sites were not correlated with belt use at a site. This quasi-random method is random with respect to this issue.

The observation interval was a constant duration (50 minutes) for each site. However, since all vehicles passing an observer could not be surveyed, a vehicle count of all eligible vehicles (i.e., passenger cars, vans/minivans, sport-utility vehicles, and pickup trucks) on the traffic leg under observation was conducted for a set duration (5 minutes) immediately prior to and immediately following the observation period (10 minutes total). These counts were used to estimate the number of possible observations so that sites could be weighted by traffic volume.

Mini-Survey Design

In order to obtain a statewide estimate of safety belt use with the least amount of cost, Minnesota chose to conduct a “mini survey” during the pre-mobilization period. The goal of the mini survey was to determine a valid statewide safety belt use rate following the sampling procedures, stratification, and methods established for the full survey. Toward this end, we randomly selected 84 sites from the full survey. The sites were selected with roughly the same proportions as the full survey for intersections and exit ramps. Scheduling of sites was completed using a new clustering and randomization of days and times. Thus, even though all 84 sites in the mini survey are found in the full survey, data are collected at them during different times of day and days of week. Analyses were conducted using the same methods and equations as used in the full survey.

Data Collection

Data collection for the survey involved direct observation of shoulder belt use, estimated age, and sex. Trained field staff observed shoulder belt use of drivers and

front-right passengers traveling in passenger cars, sport-utility vehicles, vans/minivans, and pickup trucks during daylight hours from May 1 – 14 for the mini (PRE) survey and June 10 – 23 for the full (POST) survey. Observations of safety belt use, sex, age, vehicle type, and vehicle purpose (commercial or noncommercial) were conducted when a vehicle came to a stop at a traffic light or a stop sign. Vehicles were included without regard to the state in which the vehicle was registered.

Data Collection Forms

Data were collected using personal digital assistants (PDAs). For a more detailed description of the PDA data collection process, see Appendix A. To begin, an electronic form was developed for data collection containing: a site description section and a safety belt observation section. For each site surveyed, separate electronic copies of the form were created in advance. The site description form section allowed observers to provide descriptive information including the site location, site type (freeway exit ramp or intersection), site choice (primary or alternate), observer number, date, day of week, time of day, weather, and a count of eligible vehicles traveling on the proper traffic leg. A place on the form was also furnished for observers to electronically sketch the intersection and to identify observation location. Finally, a comments section was available to identify landmarks that might be helpful in characterizing the site (e.g., school, shopping mall) and to discuss problems or issues relevant to the site or study.

The safety belt observation section of the form was used to record safety belt use, passenger information, and vehicle information. For each vehicle surveyed, shoulder belt use, sex, and estimated age of the driver and the front-outboard passenger were recorded along with vehicle type. Children riding in child restraint devices (CRDs) were recorded but not included in any part of the analysis. Occupants observed with their shoulder belt worn under the arm or behind the back were noted but considered belted in the analysis. The observer also recorded whether the vehicle was commercial or noncommercial. A commercial vehicle is defined as a vehicle that is used for business purposes and may or may not contain company logos. This classification includes vehicles marked with commercial lettering or logos, or vehicles with ladders or other tools on them.

Procedures at Each Site

All sites in the sample were visited by one observer for a period of one hour. Upon arriving at a site, the observer determined whether observations were possible at the site. If observations were not possible (e.g., due to construction), the observer proceeded to the alternate site. Otherwise, the observer completed the site description form and then moved to their observation position near the traffic control device. Observers were instructed to observe only vehicles in the lane immediately adjacent to the curb, regardless of the number of lanes present.

At each site, observers conducted a 5-minute count of all eligible vehicles in the designated traffic leg before beginning safety belt observations. Observations began immediately after completion of the count and continued for 50 minutes. During the observation period, observers recorded data for as many eligible vehicles as they could observe. If traffic flow was heavy, observers were instructed to record data for the first eligible vehicle they saw, and then look up and record data for the next eligible vehicle they saw, continuing this process for the remainder of the observation period. At the end of the observation period, a second 5-minute vehicle count was conducted.

Observer Training

Prior to data collection, members of the Minnesota Department of Public Safety, Office of Traffic Safety (OTS) staff were trained on field data collection procedures. The training of OTS staff included both classroom review of data collection procedures and practice field observations. Field observers were then hired and trained by OTS staff on the proper procedures for data collection. Each observer received a training manual containing detailed information on field procedures for observations, data collection forms, and administrative policies and procedures. A site schedule identifying the location, date, time, and traffic leg to be observed for each site was included in the manual (see Appendix B for a listing of the sites). During data collection, observers were spot checked in the field by a field supervisor to ensure adherence to study protocols.

Data Processing and Estimation Procedures

The safety belt data were entered into PDAs directly, so no data entry was required. For each site, computer analysis programs determined the number of observed vehicles, belted and unbelted drivers, and belted and unbelted passengers. Separate counts were made for each independent variable in the survey (i.e., site type, time of day, day of week, weather, sex, age, seating position, and vehicle type). This information was combined with the site information to create a file used for generating study results.

As mentioned earlier, our goal in this safety belt survey was to estimate belt use for the state of Minnesota based on VMT. As also discussed, not all eligible vehicles passing the observer could be included in the survey. To correct for this limitation, the vehicle count information was used to weight the observed traffic volumes so that an estimate of traffic volume at the site could be derived.

This weighting was done by first adding each of the two 5-minute counts and then multiplying this number by five so that it would represent a 50-minute duration. The resulting number was the estimated number of vehicles passing through the site if all eligible vehicles had been included in the survey during the observation period at that site. The estimated count for each site is divided by the actual number of vehicles observed there to obtain a volume weighting factor for that site. These weights are then applied to the number of actual vehicles of each type observed at each site to yield the weighted N for the total number of drivers and passengers, and total number of belted drivers and passengers for each vehicle type. All analyses reported are based upon the weighted values.

Estimation of Use Rates

The overall safety belt use rate for Minnesota was calculated utilizing the following procedure. The safety belt use rate for each stratum was calculated using the following formula:

$$R_s = \sum \frac{est_i}{obs_i} belted_i / \sum \frac{est_i}{obs_i} occs_i$$

Where R_s is the use rate for a stratum, i is a site in the stratum, est_i is the estimated number of possible observations had every eligible vehicle been recorded (based on the vehicle counts), obs_i is the actual number of people observed, $belted_i$ is the number of people observed using a safety belt, and $occs_i$ is the number of occupants.

Because the number of intersections among the first four strata and the number of exit ramps among the last four strata differed, the probability of an intersection or exit ramp being randomly selected differed between strata. Therefore, we painstakingly counted all intersections in the first four strata and all exit ramps in the last four strata and used these counts to weight use rates when combining them. The first four strata (intersections) were combined using the following formula:

$$R_i = \frac{\frac{4N_1}{N_{all}}R_1 + \frac{4N_2}{N_{all}}R_2 + \frac{4N_3}{N_{all}}R_3 + \frac{4N_4}{N_{all}}R_4}{\frac{4N_1}{N_{all}} + \frac{4N_2}{N_{all}} + \frac{4N_3}{N_{all}} + \frac{4N_4}{N_{all}}}$$

$$R_i = \frac{N_1R_1 + N_2R_2 + N_3R_3 + N_4R_4}{N_1 + N_2 + N_3 + N_4}$$

where R_i is the combined use rate for the first four strata (intersections), N_1 is the total number of intersections in stratum 1 and so on, and N_{all} is the total number of intersections among all four strata. The use rate for the exit ramp strata (strata 5-8) was calculated using the following formula:

$$R_e = \frac{\frac{4N_5}{N_{all}}R_5 + \frac{4N_6}{N_{all}}R_6 + \frac{4N_7}{N_{all}}R_7 + \frac{4N_8}{N_{all}}R_8}{\frac{4N_5}{N_{all}} + \frac{4N_6}{N_{all}} + \frac{4N_7}{N_{all}} + \frac{4N_8}{N_{all}}}$$

$$R_e = \frac{N_5R_5 + N_6R_6 + N_7R_7 + N_8R_8}{N_5 + N_6 + N_7 + N_8}$$

where R_e is the combined use rate for strata 5-8 (exit ramps), N_5 is the total number of exit ramps in stratum 5 and so on, and N_{all} is the total number of exit ramps among all four strata.

Because only statewide VMT for limited access roadways was available and because only 29 percent of Minnesota travel is on limited access roadways, the

statewide safety belt rate was determined weighting R_e and R_i by their VMT using the following equation:

$$R_{MN} = \frac{VMT_i R_i + VMT_e R_e}{VMT_i + VMT_e}$$

Estimation of Variance

The variances for the belt use estimates for each strata were calculated using an equation derived from Cochran's (1977) equation 11.30 from section 11.8:

$$\text{var}_{(r)} \approx \frac{n}{n-1} \sum_i \left(\frac{g_i}{\sum g_k} \right)^2 (r_i - r)^2 + \frac{n}{N} \sum_i \left(\frac{g_i}{\sum g_k} \right)^2 \frac{s_i^2}{g_i}$$

where $\text{var}(r_i)$ equals the variance within a stratum, n is the number of observed intersections, g_i is the weighted number of vehicle occupants at intersection i , g_k is the total weighted number of occupants at all sites within the stratum, r_i is the weighted belt use rate at intersection i , r is the stratum belt use rate, N is the total number of intersections within a stratum, and $s_i = r_i(1-r_i)$. In the actual calculation of the stratum variances, the second term of this equation was negligible and was dropped in the variance calculations as is common practice.

Again because the number of intersections and exit ramps differed among the strata, when the variances were combined, they were weighted by the number of intersection/exit ramps within each strata. The variances for the first four (intersection) strata were combined using the following formula:

$$\text{var}(R_i) = \left(\frac{N_1}{N_{all}} \right)^2 \text{var}(R_1) + \left(\frac{N_2}{N_{all}} \right)^2 \text{var}(R_2) + \left(\frac{N_3}{N_{all}} \right)^2 \text{var}(R_3) + \left(\frac{N_4}{N_{all}} \right)^2 \text{var}(R_4)$$

The variance for the exit ramp strata were combined using the following formula:

$$\text{var}(R_e) = \left(\frac{N_5}{N_{all}} \right)^2 \text{var}(R_5) + \left(\frac{N_6}{N_{all}} \right)^2 \text{var}(R_6) + \left(\frac{N_7}{N_{all}} \right)^2 \text{var}(R_7) + \left(\frac{N_8}{N_{all}} \right)^2 \text{var}(R_8)$$

The overall variance was determined by weighting the intersection and exit ramp variances relative to the statewide VMT for these types of roadways using the following equation:

$$\text{var}(R) = \frac{(VMT_i)^2 \text{var}(R_i) + (VMT_e)^2 \text{var}(R_e)}{(VMT_i + VMT_e)^2}$$

The 95 percent confidence band was calculated using the formula:

$$95\% \text{ ConfidenceBand} = R \pm 1.96\sqrt{\text{var}(R)}$$

Finally, the relative error or precision of the estimate was computed using the formula:

$$\text{RelativeError} = \frac{SE}{R}$$

where SE is the standard error. The federal guidelines (NHTSA, 1992, 1998) stipulate that the relative error of the belt use estimate must be under 5 percent.

RESULTS

As discussed previously, two surveys were conducted for this evaluation: a mini survey conducted prior to the mobilization campaign (PRE) and a full survey conducted after the campaign (POST). Both surveys report statewide safety belt use for four vehicle types combined (passenger cars, vans/minivans, sport-utility vehicles, and pickup trucks), in addition to reporting use rates for occupants in each vehicle type separately. Following NHTSA (1998) guidelines, these surveys included commercial vehicles. Thus, all rates shown in this report include occupants from both commercial and noncommercial vehicles. Because the mini survey is limited in scope, reliable estimates of safety belt use are only possible for strata, overall, and by roadway type. Only these variables are compared between surveys. Belt use estimates for additional variables in the full survey are also reported.

Overall Safety Belt Use

Table 2 shows the estimated safety belt use rate in Minnesota for all front-outboard occupants traveling in passenger cars, sport-utility vehicles, vans/minivans, and pickup trucks in the front-outboard positions in Minnesota during the two survey periods. The "±" value following the use rates indicate a 95 percent confidence interval around the percentage. As shown in this table, the statewide safety belt use rate prior to the *Click it or Ticket* campaign was 87.4 ± 3.5 percent and 91.3 ± 1.5 percent afterwards. Although belt use after the campaign was higher than the PRE rate, this difference was not statistically significant. The post-campaign rate was also slightly lower than the statewide rate of 92.3 percent found last year (Eby, Vivoda, & Cavanagh, 2010). The relative errors for the statewide safety belt use rates were well below the 5 percent maximum required by NHTSA: 2.0% for the PRE survey and 0.8% for the POST survey).

Estimated belt use rates and unweighted numbers of occupants (N) by stratum are also shown in Table 2.

Table 2: Safety Belt Use Rates and Unweighted Ns as a Function of Survey, Stratum, Roadway Type, and Overall Statewide Safety Belt Use				
	PRE (Mini)		POST (Full)	
	Percent Use	N	Percent Use	N
Stratum 1 (High, Intersections)	94.0	608	91.4	1,424
Stratum 2 (Hennepin, Intersections)	94.0	676	94.0	2,159
Stratum 3 (Medium, Intersections)	89.4	460	92.6	1,015
Stratum 4 (Low, Intersections)	83.0	365	87.3	1,335

Stratum 8 (Low, Exit Ramps)	77.5	229	92.6	953
Minnesota, Intersections	87.6	2,109	90.3	5,933
Minnesota, Exit Ramps	87.0	1,519	93.7	4,994
STATE OF MINNESOTA	87.4 ± 3.5	3,628	91.3 ± 1.5	10,927

Safety Belt Use by Subcategory (Post, Full Survey Only)

Vehicle Type and Stratum. Estimated belt use rates and unweighted numbers of occupants by stratum and vehicle type are shown in Tables 3a through 3d. Within each vehicle type we find few systematic differences in safety belt use by stratum. However, comparing across vehicle types and strata, we find that safety belt use is lower for pickup truck occupants in nearly all strata. Thus, enforcement and public information and education (PI&E) programs should continue to target pickup truck occupants.

Table 3a. Percent Shoulder Belt Use by Stratum (Passenger Cars)

STATE OF MINNESOTA	83.7 ± 3.1	1,538

Time of Day. Estimated safety belt use by time of day, vehicle type, and all vehicles combined is shown in Table 4. Note that these data were collected only during daylight hours. There was little systematic difference in belt use by time of day for any of the vehicle types or for all vehicles combined.

Day of Week. Estimated safety belt use by day of week, vehicle type, and all vehicles combined is shown in Table 4. Note that the survey was conducted over a 2-week period. Belt use clearly varied from day to day, but no systematic differences were evident.

Weather. Estimated belt use by prevailing weather conditions, vehicle type, and all vehicles combined is shown in Table 4. A small minority of sites were observed during rainy weather conditions, yet these sites continue to show low use of safety belts, as was been found previously (Eby, Vivoda, & Cavanagh, 2005, 2006, 2007, 2008, 2009, 2010). This finding deserves further investigation. There was essentially no difference in belt use whether it was sunny or cloudy during data collection; a common finding in safety belt research.

Sex. Estimated safety belt use by occupant sex, type of vehicle, and all vehicles combined is shown in Table 4. Estimated safety belt use is consistently at least 5-6 percentage points higher for females than for males for all vehicle types combined and for each separate vehicle type, except for vans and minivans.

Age. Estimated safety belt use by age, vehicle type, and all vehicle types combined is shown in Table 4. As there were very few 0-to-10-year olds observed in the current study, the estimated safety belt use rate for this age group may not be meaningful. Excluding this group, we found that belt use was high for the 11-15-year olds. Unlike in previous years, belt use rates for the 16-to-29-year-old age group were about the same as the rates for the next highest age group. This pattern shows that new drivers and young drivers (16-to-29 years of age) have been positively influenced by the Click It or Ticket campaign.

Seating Position. Estimated safety belt use by position in vehicle, vehicle type, and all vehicles combined is shown in Table 4. This table shows that for all vehicle types combined and each vehicle separately, belt use generally did not differ systematically by seating position.

Age and Sex. Table 5 shows estimated safety belt use rates and unweighted numbers (N) of occupants for all vehicle types combined by age *and* sex. The belt use rates for the two youngest age groups should be interpreted with caution because the unweighted number of occupants is quite low. Belt use for females in all age groups was equal to or higher than for males. However, the absolute difference in belt use rates between sexes varied depending upon the age group. Belt use for women age 16-29 was 8.2 percentage points higher than for man in the same age group.

DISCUSSION

The main purpose for conducting this study was to determine the effectiveness of Minnesota's May 2011 *Click It or Ticket* Mobilization campaign by measuring belt use before and after the campaign. Our results showed that statewide seat belt use in Minnesota was higher after the mobilization campaign, but this difference was not statistically significant. Both rates were higher than the national rate of 84% found in 2009 (Chen & Ye, 2010).

A secondary purpose of this research was to continue monitoring the progress of Minnesota's efforts to increase seat belt use statewide by examining trends in a full statewide survey. Analysis of seat belt use by the various subgroups showed that belt use continues to be high in many areas. Of particular note is the high belt use that was found for vehicle occupants age 16-29. Overall, this rate was higher than 90 percent and was nearly the same as the rate for occupants age 30-64. This result indicates that the *Click it or Ticket* campaign reached and affected its target audience.

There are, however, still some areas on which Minnesota could continue to focus efforts to increase seat belt use. Occupants of pickup trucks define a unique population that exhibits low seat belt use in Minnesota, and may therefore benefit from specially designed programs. Research has shown that the main demographic differences between the driver/owners of pickup trucks and passenger cars is that driver/owners of pickup trucks are more likely to be male, have higher household incomes, and lower educational levels (Anderson, Winn, & Agran, 1999). Work by the Center for Applied Research (NHTSA, 2004) with rural pickup truck drivers explored why these occupants wear, or do not wear, safety belts. The following reasons were given for nonuse of safety belts: vehicle size protects them from serious injury; safety belt not needed for short or work trips; fear of being trapped in vehicle after a crash; inconsistency between belt law and motorcycle helmet law; and opposition to government mandate. Reasons given for use were: presence of family or friends; travel on interstate highways; travel during inclement weather; and when not traveling in their pickup truck. This information provides a starting point for the development of programs designed to influence pickup truck occupant safety belt use, as efforts to encourage belt use by occupants of pickup trucks are warranted. The Center for Applied Research study also suggests that passage of a mandatory motorcycle helmet use law might also increase belt use among pickup truck drivers (NHTSA, 2004).

We also discovered large differences in safety belt use between males and females, in particular for the 16-29 year-olds. Understanding why there is a difference in belt use between males and females is very important. In the current survey there was a belt use difference of 6.7 percentage points between the sexes overall. According to the Motor Vehicle Occupant Safety Survey, when safety belt non-users and part-time users were asked why they did not wear belts, males and females give different reasons (Block, 2000). Females state "I forgot to put it on" as the most important reason for non-use, while males list "I'm only driving a short distance" as the reason most important to them. An analysis of the types of answers given for non-use by sex revealed that males tend to report reasons that are related to a lower perception of risk (e.g. low probability of a crash or receiving a citation), while more of the answers given by female non-users and part-time users are related to discomfort and forgetting. Traffic safety professionals in Minnesota could use this information for the development of programs aimed at increasing belt use among males.

APPENDIX A: PDA Data Collection Details

In the current study all data collection was conducted using Personal Digital Assistants (PDAs). The transition from paper to PDA data collection was made primarily to decrease the time necessary to move from the end of the data collection phase of a survey to data analysis. With paper data, there is automatically two to three weeks of additional time built-in while the paper data are being entered into an electronic format. Before making this transition, a pilot study was conducted to compare data collection by PDA to paper. Several key factors were tested during the pilot study including accuracy, volume (speed), ease of use, mechanical issues (i.e. battery life), and environmental issues (i.e. weather, daylight). The pilot study found PDA use to be equal to, or better than paper data collection on every factor tested. Before making the change to PDA data collection, electronic versions of the *Site Description Form* and *Observation Form* were developed (these have since been combined into a single electronic form). The following pages show examples of the electronic form and discuss other factors related to using PDAs for safety belt data collection.

The goal of adapting the existing paper forms to an electronic format was to create electronic forms that were very similar to the paper forms, while taking advantage of the advanced, built-in capabilities of the PDA. As such, the electronic data collection form incorporated a built-in traffic counter, used the PDA's calendar function for date entry, and included high resolution color on the screens. The site description form portion of the data collection form is divided into five screens. The first screen (Figure 2) allows users to type in the site location (street names and standing location). Observers use the PDA stylus to tap on the appropriate choices of site type, site choice, and traffic control. If a mistake is made, the observer can change the data they have input, simply by tapping on the correct choice. All selected choices appear highlighted on the screen.

Figure 2: Site Description Form – Screen 1.

Screens 2 and 3 are shown in Figure 3. As seen in this figure, observers enter their observer number, the weather, day of week, and median information, simply by tapping the appropriate choice on the display list. Screen 3 allows users to sketch in the intersection and show where they are standing, and to record the start time for the site.

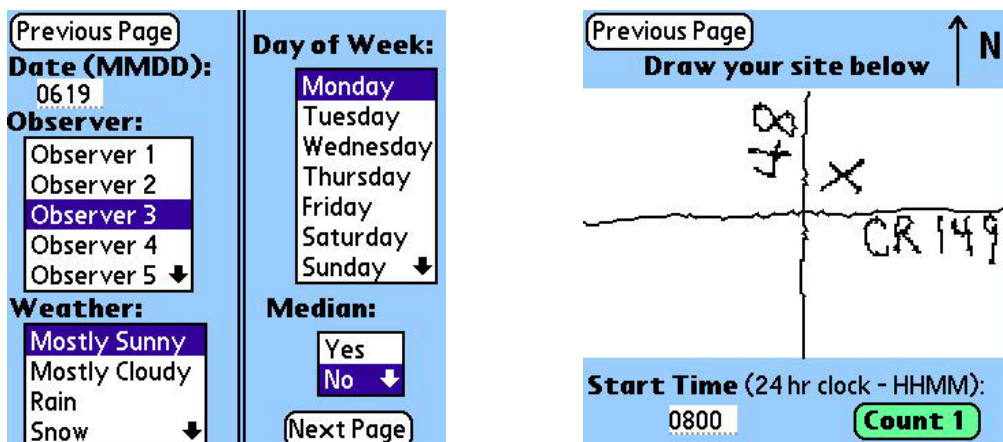

Figure 3: Site Description Form - Screens 2 and 3

In the past, observers had to put away their paper form, get out a mechanical traffic counter, and begin a traffic count after entering the start time. Using a PDA, it is possible to incorporate a traffic counter directly into the site description portion of the data collection form¹. Figure 4 shows an example of the electronic traffic counter (Screen 4). To count each vehicle that passes, observers tap on the large "+" button. The size of this button allows the observer to tap the screen while keeping their eyes on the roadway. Each tap increases the count that is displayed at the top of the screen. If a mistake is made, the observer can decrease the count by tapping on the small "-" button on the left of the screen.

¹The PDA traffic counting method was compared with a mechanical counter during the pilot testing and no difference was found between the two methods.

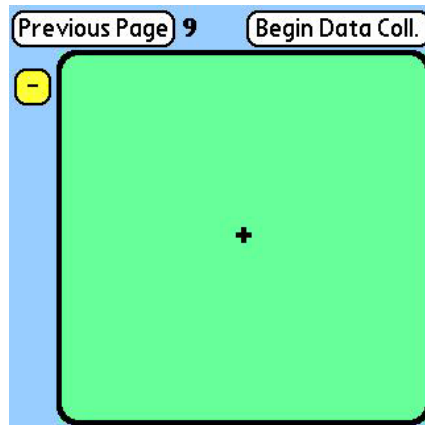

Figure 4: Site Description Form – Screen 4

The last screen of the electronic *Site Description Form*, shown in Figure 5, allows the user to enter the end time of the site observation and interruption (if any). Finally, observers can type in any comments regarding the site or traffic flow that may be important.

Figure 5: Site Description Form - Screen 5

To allow for easier data entry, the observation portion of the electronic data collection form was divided into three screens, one for vehicle information, one for driver information, and one for front-right passenger information. As shown in Figure 6, each screen is accessible by tapping on the appropriate tab along the top of the screen. The screens have also been designed with different colors, with the vehicle screen yellow, driver screen blue, and passenger screen green. As shown below, the first screen that

appears in the form is the vehicle screen. Each category of data, along with the choices for each category, are displayed on the screen. As in the Site Description Form, users simply tap on the choices that correspond to the motorist that is being observed. These data then appear highlighted on the screen. Since most vehicles are not used for commercial purposes, "Not Commercial" is already highlighted as a default. If the vehicle is commercial, that choice can be selected from the list.

Figure 6: Observation Form - Vehicle Screen

Figure 7 shows the driver and passenger screens. Because most motorists are not actively talking on a cellular phone while driving, "No Cell Phone" is already highlighted as the default. "No Passenger" is also already marked as the default choice because most vehicles have only a driver present. Once data are complete for one vehicle, observers tap the "Next Vehicle" button to continue collecting data.

Figure 7: Observation Form - Passenger and Vehicle Screens

Each PDA also had a built-in cellular phone as well as wireless e-mail capability. At regular intervals, observers e-mailed completed data directly from the PDA to the project supervisor. Data collection forms from completed sites were “zipped,” using a compression program, and then transmitted directly to a pre-determined e-mail account. The e-mailing of data allowed the field supervisor to immediately check data for errors, and begin to compile a data analysis file as the project progressed.
